#### ABSTRACT:

The present invention provides a method and apparatus for identifying and minimizing the use of cloned communicating devices which communicate with a host device. The method requires that the communicating devices send a transaction specific code and an identification code, along with each communication wherein the transaction specific code changes between each communication. One communicating device, either the authentic device or a fraudulent device might communicate with the host successfully any number of times. However, when a second devices attempts communication whether that device is the authorized device or fraudulent device, the host device will receive a transaction specific code which is inconsistent or out of sequence with that expected by the host. The host device will preferably disallow all further communications involving the particular identification code until the

authorized user can be contacted and the transaction specific code reset or even a new set of transaction specific codes are provided. Alternatively, upon detection of the inconsistent transaction specific code, the host computer may prompt the user for information specific to the authorized user that is not stored in the communicating device and would not be readily available to the clone device or the user of the clone device.

TITLE: Method and apparatus for securing digital communications

Abstract Text (1):

The present invention provides a method and apparatus for identifying and minimizing the use of cloned communicating devices which communicate with a host device. The method requires that the communicating devices send a transaction specific code and an identification code, along with each communication wherein the transaction specific code changes between each communication. One communicating device, either the authentic device or a fraudulent device might communicate with the host successfully any number of times. However, when a second devices attempts communication whether that device is the authorized device or fraudulent device, the host device will receive a transaction specific code which is inconsistent or out of sequence with that expected by the host. The host device will preferably disallow all further communications involving the particular identification code until the authorized user can be contacted and the transaction specific code reset or even a new set of transaction specific codes are provided. Alternatively, upon detection of the inconsistent transaction specific code, the host computer may prompt the user for information specific to the authorized user that is not stored in the communicating device and would not be readily available to the clone device or the user of the clone device.

Application Filing Date (1):

19970903

Brief Summary Text (3):

The present invention relates to the security of communications, and more particularly to a method and apparatus for combating the use of cloned, fraudulent or unauthorized communicating devices, such as cellular telephones, credit cards and computer terminals.

Brief Summary Text (5):

Communication signals are used widely in many different or interrelated fields, such as credit card authorization systems, cellular telephone and radio communications, satellite transmissions, telephone calls, computer networks and modem connections, automated teller machine transmissions, direct broadcast television, garage door openers, automobile remote devices and the like. While each of these fields may have different communication protocols, performance objectives and technical constraints, each of the fields have at least some concern for the security of the communication. Specific security concerns may deal with the content of the communication itself (often protected by encryption methods), the integrity of the communication (often protected by error-checking and anti-virus software), and authorized access to the communication (often protected by account codes and passwords).

Brief Summary Text (6):

Unauthorized access to communications and communicating devices has become a problem in many of the fields mentioned. Computer networks have been broken into by determining authorized account codes and passwords, thereby gaining access to proprietary information or computing capabilities Credit card transactions may be charged by an unauthorized person by merely possessing a lost or stolen card. Cellular telephones may be duplicated or cloned to produce a large number of fraudulent telephones having the same account codes and personal identification codes as a lost or stolen authentic cellular telephone. Attempts to combat these unauthorized communications has taken many forms.

Brief Summary Text (8):

For example, a serious problem in existing cellular telephone systems may be referred to as the "false mobile station" syndrome. It is presently possible to copy the entire memory contents of a mobile station and to use that information to manufacture clones which can demand and receive service from the network. Cellular phones may be cloned by reading the entire memory contents of the phone, including its identification codes, secret keys, internally stored personal identification codes, signatures, etc., and writing the same codes into any number of similar "clone" phones. The cloning procedure can become quite sophisticated and may include software modifications which replace physically stored information with electronically stored information so that a number of stored mobile station identities may be cyclically rotated within one fraudulent mobile station and used to imitate several authentic mobile stations.

Brief Summary Text (9):

Similar breaches of communications have occurred in financial transactions involving credit cards. Typically, the information on a lost or stolen credit card can be electronically read and duplicated on any number of credit cards. The cards are then distributed and used until either the credit limit of the card is surpassed or the card is reported stolen or lost to the credit card company. Significant actual losses are experienced each year due to the use of such "cloned" credit cards.

Brief Summary Text (10):

Many communication systems, including cellular telephone networks and credit card authentication or authorization systems, comprise a vast number of distributed communicating devices (i.e., mobile cellular phones or credit cards and credit card readers) that transmit data to a central computer system in charge of determining whether or not to allow the communication to go through. The central computer system may execute an authorization algorithm to determine if the credit card has a valid account or identification number, if there is an available balance of credit and, perhaps, if a valid personal identification number has been given or entered. However, sophisticated thieves have been able to duplicate the credit card with valid identification numbers and determine even the personal identification number.

Brief Summary Text (11):

Similarly, computer network communications or computer-to-computer communications may include files that are locked, password protected, zipped and/or encrypted for various reasons, including the security of the content of the communication. Password protection provides a limited degree of security, primarily protecting a communication from being accessed by persons who casually encounter the file, but this security can still be violated. Encryption is perhaps the most secure means for preventing outsiders from obtaining the content of the communication and, therefore, is in widespread use by banks and other financial institutions throughout the world for many or all of their electronic transactions.

Brief Summary Text (15):

The present invention provides a method of authenticating a communication, comprising (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with a transaction specific code from the first sequence; (e) refusing communications having a transaction specific code that is different from the transaction specific code expected by the second communicating device; and (f) incrementing the pointers in both the first and second communicating devices. The first and second sequences of transaction codes may be stored in a database or calculated according to various algorithms.

Brief Summary Text (16):

The first and second communicating devices may take on various forms and functions. For example, the first communicating device may be a credit card and the second communicating device a central clearinghouse; the first communicating device may be a cellular telephone and the second communicating device a cellular network; the first communicating device may be a garage door remote and the second communicating device a garage door opener; the first communicating device may be an automobile remote unlock device and the second communicating device an automobile remote unlock

device receiver; the first communicating device may be a computer and the second communicating device another computer; and the first communicating device may be a direct broadcast television system and the second communicating device a television receiver. It should also be recognized that the communication may proceed through transmissions selected from electrical, radio and optical.

Brief Summary Text (17):

The invention also provides a method of authenticating a communication, comprising: (a) providing a first communicating device with a first identification code and a first sequence of transaction specific codes; (b) providing a host communicating device with the first identification code and the first sequence of transaction specific codes; (c) setting pointers in the first sequence of transaction specific codes of both the first communicating device and the host device at the same transaction specific code; (d) transmitting a communication from the first communicating device to the host communicating device along with the first identification code and the transaction specific code associated with the pointer in the first sequence of transaction specific codes; (e) disallowing communications transmitted with the first identification code that have a transaction specific code that is different from the transaction specific code associated with the pointer in the first sequence of transaction specific codes; and (f) incrementing the pointers in the first communicating device and the host communicating device.

Brief Summary Text (18):

The invention further provides a method of authenticating a communication, comprising: (a) providing each of a plurality of communicating devices with a device identification code and an associated sequence of transaction specific codes; (b) providing a host communicating device with an identical copy of each of the device identification codes and the associated sequences of transaction specific codes; (c) setting pointers in the communicating device and the host device at the same transaction specific code in the sequence of transaction specific codes associated with each identification code; (d) transmitting a communication from one of the communicating devices to the host communicating device along with the device identification code and the transaction specific code associated with the pointer in the sequence of transaction specific codes; (e) disallowing communications transmitted with the device identification code that have a transaction specific code that is different from the transaction specific code associated with the pointer in the sequence of transaction specific codes; and (f) incrementing the pointers in the communicating device and the host communicating device.

Brief Summary Text (19):

The invention also provides a method of detecting the existence of two or more communicating devices having the same identification code comprising the steps of: (a) transmitting an identification code and a transaction specific code from a first communicating device to a host device; and (b) comparing the transaction specific code received by the host device with a next expected transaction specific code for a communicating device having the particular identification code.

Brief Summary Text (20):

Further, the invention provides a method of communicating between a communicating device and a host device, comprising the step of transmitting an identification code and a transaction specific code to the host device wherein the identification code is unique to the communicating device and the transaction specific codes are predetermined and known by the communicating device and the host device for the purpose of allowing the host device to detect the usage of a fraudulent communicating device having the same identification code. The method may also comprise changing the transaction specific code for subsequent attempted communications. The method may further comprise disallowing communications having an improper transaction specific code.

Brief Summary Text (21):

The invention additionally provides a method of disallowing communications initiated by fraudulent communicating devices comprising (a) receiving an identification code and a transaction specific code from a communicating device; (b) searching a list of transaction specific codes in the host device; and (c) having a predetermined sequence of transaction specific codes for the next expected transaction specific code from a device having the received identification code.

Brief Summary Text (22):

Finally, the invention provides a method of resynchronizing the next expected

transaction specific code between communicating devices by matching a pattern of transaction specific codes in the communicating device with a pattern of transaction specific codes in the host device.

Detailed Description Text (2):

The present invention provides a method and apparatus for identifying and approving authentic communications. Such method and apparatus are important for preventing unauthorized communications through various communication media, including electronic, audible, visual or the like. Perhaps the most widely used media for communications in business and personal applications include electronic and radio frequency communications such as those involving computer to computer transfers, credit card authorization and approval, cellular telephone calls and data transmissions, satellite broadcasts, automated teller machine transactions, and other electronic communications. For various reasons, it is frequently desirable or necessary for access to these communications to be restricted to authorized persons, authorized equipment, authorized locations, and the like. While the set of criteria necessary to authenticate a transmission or communication may be short and simple or long and complicated, the present invention proposes a simple, yet effective, method for preventing unauthorized communications. More particularly, the present invention prevents the successful use of multiple cloned or otherwise fraudulent devices, and limits the use of even a single cloned or otherwise fraudulent device to the time interval between the "cloning" event and the next authentic communication. Such time interval may be as long as several days (for example an infrequently used credit card) or as short as fractions of a second (for example in electronic financial transactions between institutions).

Detailed Description Text (3):

In one aspect of the invention, a method is provided for preventing the cloning and fraudulent use of various authentic communicating devices. Attempts to increase the complexity of the communicating device or the difficulty of successfully duplicating the device have met with limited success, because once the device has been successfully cloned, unauthorized communications may be accomplished. The methods of the present invention do not depend upon the complexity of the physical communicating device or the magnitude of possible security codes or keys, but rather, the present invention provides for transmitting a transaction specific code along with identification codes and the communication itself in accordance with a predetermined set of transaction codes known to a central authorizing device or host. These codes may take various forms including, but not limited to, numeric, alphabetic, alpha numeric and the like and may be transmitted through various media including, but not limited to, digital or analog electronic signals, radio waves, light waves, chemical or other optical means, other wave forms, and the like. The transaction specific code may be as simple as a sequential set of algorithmically generated numbers, such as 1 through 100, or some random set of codes predetermined and stored in both the communicating device and the host communicating device.

Detailed Description Text (4):

The invention operates on the principal that when an authorized communicating device transmits a series of communications, with each communication accompanied by a transaction specific code, the host or receiving device, such as a computer, will expect to receive the transaction specific codes in a particular, predetermined sequence. So long as subsequent communications contain a transaction specific code consistent with the existence of only one authorized communicating device having a given identification code, then the communication may be allowed or authorized. In the event that communications are initiated containing transaction specific codes which indicate the presence of duplicate communicating devices, then the communications will be disallowed. The methods just described do not address or prevent the physical cloning of the communicating device, but rather prevent the successful use of cloned devices over a period of time or the successful access to a communication over a period of time.

Detailed Description Text (5):

In another aspect of the invention, subsequent communications may be re-initiated by resetting the pointer at a different point in the sequence of predetermined codes in the authorized communicating device. In this case, the host device must also be informed of the reset point in order maintain synchronization. Alternatively, the communicating device and host device may be provided with a new set of transactions specific codes. The provision of new codes may be accomplished in any manner, manual or automatic, but automatic or periodic updating of codes may require modification of existing communicating devices which do not have sufficient receiving and storing

capabilities.

Detailed Description Text (6):

Typical cloning patterns, such as those experienced in the credit card and cellular telephone markets, involve the loss or theft of a single authorized communicating device, i.e., the physical credit card or cellular telephone, which is then duplicated to provide a large number of fraudulent devices which operate identical to the authorized communicating device. In accordance with the prior art, the successfully cloned, yet fraudulent, devices were allowed to communicate successfully leading to losses of millions or billions of dollars. As indicated above, the methods of the present invention do not rely upon device designs which are presently difficult to copy or clone, but provides a method by which the use of two or more devices, such as the authorized device and one fraudulent device or multiple fraudulent devices, is identified by the host device upon receiving a transaction specific code which is inconsistent with the predetermined set of codes.

Detailed Description Text (7):

In one aspect of the invention, the degree of inconsistency in the transaction specific codes can be modified or tailored to a specific application. For example, a transaction specific code may be sufficient to allow a communication to be authorized so long as it falls within a particular range of transaction specific codes expected by the host. More particularly, in the situation where the transaction specific codes are a sequence of numbers from 1 through 100 listed in numerical order, a sequence of communications would be expected to include transaction specific codes that fall in a sequence, such as 1, 2, 3, 4, 5, etc. However, for specific applications such as credit card use, it may be acceptable to allow or authorize communications containing transaction specific codes that are within a range of codes next expected by the host. Therefore, if the host was expecting to receive transaction specific codes of 1, 2, 3, 4, 5, 6, 7, 8, etc. over a series of communications, then a series of communications containing transaction specific codes of 1, 2, 4, 5, 7, 8 would be allowed if the host device were programmed with a tolerance of two codes. It is also anticipated that the host computer may take additional action if the transaction code tolerance is required too frequently.

Detailed Description Text (8):

It should be recognized that the set of codes to be transmitted by the authorized communicating device and stored in a database within the host device may comprise a mere list or database of transaction specific codes established in a given order. While the fields of the database are maintained in a certain sequence, the transaction specific codes within those fields may vary in any manner. Therefore, the database programmed into the communicating device and the host device may have a database segment containing the numerical transaction specific codes of 54, 86, 32, 64, 35, and 97. To an outside observer or someone intercepting these codes, the code would appear to be random or at least undeterminable. However, the host device knows what the next expected transaction specific code is to be, i.e., if the previous transaction specific code was 86, then the next expected transaction specific code is 32, but transaction specific code of 64 would be accepted if the tolerance were set at two fields. This ability allows the host computer to determine whether or not the communication is authentic. In this context, the concept of tolerance no longer implies that the transaction specific code has a numerical value within a certain range, but rather that the transaction specific code may be found within a range of fields within the database forwardly adjacent to a field containing the next expected code. The ability of the database to contain any number of transaction specific codes of any length or type of signal vastly increases the difficulty of predicting the next transaction specific code. However, even in the simplest of embodiments, where the transaction specific codes comprise a sequence of numbers in numerical order, the invention still prevents widespread cloning in the manner described above. Furthermore, a simple embodiment of the present invention allows the host computer to dispense with an actual database but rather comprise a single data register or memory location for storing either the last transaction specific code, the next expected transaction specific code, or some equivalent means of tracking used or soon to be used codes.

Detailed Description Text (9):

While the foregoing discussion has dealt primarily with detecting unauthorized communicating devices, the present invention may also include the ability to detect unauthorized users. In many applications, including credit card authorization and

approval and cellular telephone communications, it is frequently desirable to verify that the communication is being initiated by an authorized user. The inclusion of a user authorization system is beneficial for reducing the use of the authentic communicating device when it has been stolen or lost. Losses due to the use of lost or stolen communicating devices is also very significant, but is inherently limited to the capacity of via the authorized communicating device itself, i.e., one communication at a time, a credit limit, etc. Furthermore, the use of lost or stolen communicating devices by unauthorized users may be restricted by the use of user specific codes, such as a personal identification number (PIN), finger print, password, voice command and the like.

Detailed Description Text (10):

In another aspect of the invention, the host device and/or the communicating device may be programmed to verify the identity and authenticity of the device alone or in combination with the user. In one example, the host computer may first verify that the communication is being initiated from an authorized communicating device, then prompt the user to enter a personal identification code (PIN) indicating that the user is also authorized. Only upon satisfaction of these two criteria is the communication be allowed to proceed. It should be recognized that the host device could be programmed to verify these two codes, or other additional codes and authorizations, in any order. In another example, the communicating device itself may require the successful input of a personal identification code prior to enabling or energizing the transaction specific code, any portion of the device identification code or even some portion of the communication itself.

Detailed Description Text (11):

A still further aspect of the invention provides for automatic re-synchronization of the transaction specific codes following one or more unauthorized communications. Re-synchronization methods according to the present invention may be achieved by programming the host device to reset the pointer in a database of transaction specific codes for a particular identification code upon receiving a series of attempted communications having a series of transaction specific codes that match a portion of the database. For example, after receiving an attempted communication having a transaction specific code that is not the next expected transaction specific code or within the range of tolerance, no further communications using the same identification code can proceed until the transaction specific codes of the communicating device and the host are re-synchronized. If the host device is programmed to allow re-synchronization after receiving three transaction specific codes (i.e., 12, 13, 14) that match a portion of the host database (i.e., 10, 11, 12, 13, 14, 15, 16, etc.) for the given identification code, then the pointer in the host database is reset for the next transaction specific code (i.e., 15) in the database. Subsequent communications may proceed in accordance with the aforementioned methods. It may be beneficial to a separate range of tolerance for re-synchronization in order to prevent re-synchronization at a dramatically different point in the sequence of transaction specific codes.

Detailed Description Text (12):

Another aspect of the invention provides for periodically incrementing, or otherwise moving, the pointers in the transaction specific codes in both the communicating device and the host device. The periodic movement of the pointer is advantageous because it effectively shortens the time period or "window of opportunity" in which a cloned device having a full and correct set of transaction specific codes may operate. For example, if an authentic communicating device is infrequently used, a cloned device may initiate successful communications until such time as the authentic communicating device is used again. However, if the authentic communicating device and the host device are designed or programmed for periodically moving their database pointers, in accordance with a predetermined algorithm, then the cloned device may initiate successful communications only until the next movement of the database pointers. Specifically, the database pointers may be incremented by one or more fields after specific time intervals, i.e., ten minutes, an hour, a day, etc.

Detailed Description Text (13):

FIG. 1 is a schematic diagram of an identification and authorization system 10 in accordance with the present invention. A communicating device 12 generates and transmits a communication 16 to a host device 14, wherein the communication 16 comprises an identification code 18, a transaction specific code 20 and the content 22 of the communication itself. Note that both the communicating device 12 and the host device 14 contain similar databases, lists or tables 24, 26, respectively,

having a plurality of fields 28, 30 containing the same transaction specific codes in the same sequence. Prior to the first communication, a pointer in both databases is directed to the same field containing the same transaction specific code.

Detailed Description Text (14):

It should be recognized that the host device 14, or perhaps even communicating devices which are capable of transmitting or receiving communications from or to a plurality of other devices, may have a plurality of n lists of transaction specific codes, where n is the number of authorized identification codes, such as the identification code 32 having the list 26. Each of the n lists in the host device 14 will have a pointer, such as pointer 34, which indicates the next expected field in the sequence of m fields in the list or database 26 which, in turn, contains the next expected transaction specific code (i.e., TS Code=ABC123). Similarly, the database 24 of the communicating device 12 has a pointer 36 which indicates the next transaction specific code (i.e., ABC123) to be transmitted along with the identification code 38. Upon receiving the communication 16, the host device 14 determines the identification code 18 and looks for the identification code among the n authorized identification codes. Then the host device 14 compares the transaction specific code 20 received from the communicating device 12 with the transaction specific code 30 indicated by the pointer 34.

Detailed Description Text (15):

During subsequent communications, the transmission from the communicating device 12 will contain subsequent transaction specific codes 28 from the database 24. Errant or failed communications may lead to the pointer 36 of the communicating device 12 incrementing to the next field in the database 24 without the communication ever being received by the host device 14 and, consequently, without the database 26 of the host device 14 ever being incremented. This and other similar situations represent a benefit of using the tolerance feature described above. If the host device 14 receives a transaction specific code 20 falling in the database within a reasonable range of fields, typically only fields in the forward direction, then the communication is allowed to proceed. For example, if the tolerance is set to three fields 40 and the pointer 34 is set at the field containing "ABC123", then the host device 14 may authorize communications having an identification code 32 and a transaction specific code of "ABD123", "MOON" or "FRED", but not "DOG" (since it is not in a forwardly directed field) or "64" (since it is outside the tolerance range of 3). In this example, if the communication was authorized on the basis of a transaction specific code of "FRED", then the database pointer 34 in the host device 14 would preferably be reset to a next expected transaction specific code of "64" which matches that of the communicating device 12.

Detailed Description Text (16):

It should be recognized that communications having acceptable identification codes and transaction specific codes may be further subject to verification of other conditions, such as a personal identification number (PIN) and the like. Examples of other conditions or criteria useful for determining whether or not to authorize a particular communication include the location from which the communication is initiated, the frequency with which communications occur, the type of communication being attempted, the content of the communication itself, and discrepancies between time and space which indicate the unlikely use of a single device suggesting cloning. Other useful criteria will become apparent in specific applications.

Detailed Description Text (17):

As shown in FIG. 1, the communicating device 12 preferably includes a member 42 for providing the content 22 of the communication 16 to a transmitter 44. The actual transmission may be initiated in any number of manners, but specifically may be initiated with a "send" button 46, such as that on a cellular telephone or by the act of swiping a credit card. The host device 14 preferably includes a receiver 48 and a central processing unit (CPU) 50. The CPU 50 is provided with the communication 16 from the receiver 48 and executes a series of steps in order to authenticate the communication.

Detailed Description Text (18):

FIG. 2 is a conceptual diagram which is useful for arriving at a full understanding of the one aspect of the present invention. The diagram of FIG. 2 presents a set of keys on a ring 52 and a set of locks 54 in a door 56 which operate analogous to the present invention. The key ring 52 (communicating device) includes a fob 58 (identification code) and a plurality of keys 60 (transaction specific codes). The door 56 (host device) includes a plurality of locks 62 (expected transaction

specific codes) for each fob (identification code) which can only be unlocked by using a specific key (transmitted transaction specific code). The locks 62 (transaction specific codes) in the door (host) are rotated (incremented) in the direction of arrow 64 by a mechanism each time the door is unlocked. Similarly, the keys (transaction specific codes) on the key ring 52 are rotated (incremented) each time a key is used.

Detailed Description Text (19):

The door and key ring are initially used as shown, with the key a and lock A ready for the first unlocking of the door (communication). When key a unlocks the door with lock A, then the door is open for a transaction to pass therethrough. Note that the transaction does not need to have any actual connection with the key nor the lock. Anything may move through the doorway once the door is unlocked.

Detailed Description Text (20):

When the transaction is completed, the door is closed, the next lock in the rotation is moved into place and the keys are rotated around the ring in preparation for the next unlocking. In this case, the key b is positioned as the next key to be used and the lock B is positioned as the next operating lock in the door.

Detailed Description Text (21):

To enable the next transaction, key b is used with lock B. The door is unlocked and open for the transaction as before. When this second transaction is completed, the door is closed and both the keys are rotated to key c and the locks are rotated to lock C. Note that this transaction system operates with synchronous rotation of the keys and locks. Only one key on the ring will unlock the door for any specific transaction, thereby providing much greater security than a more complex key.

Detailed Description Text (25):

This mechanical analogy illustrates four features of sequential synchronized keys: (1) it is difficult to guess the next key; (2) the keys are not specifically related to the content of the transaction; (3) there are various ways of guarding the lock from tampering; and (4) there are various ways of guarding the keys from duplication.

Detailed Description Text (27):

In a further aspect of the invention, the successful entry of a personal identification number or code may also result in the generation of a visual indicator on a display 76 that signifies successful entry. Such a visual indicator would be useful in applications where the initiation of the communication is attended by a representative interested in the proper authorization of the communication, for example, a sales clerk in a retail outlet which either does not have electronic authorization equipment or such equipment is presently inoperable. A visual indicator may also be useful in situations where electronic verification equipment is available, but the sales representative is available to monitor the number of unsuccessful attempts at entering the personal identification number. In any of these circumstances, the sales clerk could require the visual indicator prior to proceeding with the transaction or communication.

Detailed Description Text (28):

Still referring to FIG. 2, the card 70 of the present invention makes use of conventional magnetic media supplemented with at least one electronically generated bit of information. This electronically generated bit may occur anywhere in the magnetic strip 72, including the region 78 containing a cyclic redundancy check or other verification code such as a check bit system, the region 80 containing an identification number, the region 82 containing the transaction specific code, or any other region. Further, the electronically generated bit may comprise its own region 84, perhaps indicating to the host through a card reader that the user is authorized, i.e., has successfully entered the personal identification number.

Detailed Description Text (29):

Operation of the card 70 is facilitated by an energy source 86, such as a lithium battery or a solar cell. The energy source 86 must provide sufficient power for any device on the card, such as the display 76, an electronically generated bit (shown here as located in the region 82), the keypad 74 and a CPU 88. The CPU 88 may be entirely embedded within the card 70 or located as desired for protection of the CPU or ease of manufacture. The CPU 88 is responsible for verifying correct PIN entry from the keypad 74, providing a signal to display 76, controlling the electronically generated bit(s) (shown here in region 82), and other various functions that are

necessary or desirable to the function of the card. Further, the card 70 may comprise a multifunction device such as a calculator, etc.

Detailed Description Text (32):

The present invention encompasses the use of any number of electronically generated bits or conductive wires 90. However, in order to merely energize the card and complete a coherent transmission, only a single wire is necessary. However, in other embodiments, it is anticipated that multiple wires will be desirable. For example, transaction specific codes may be provided by the internal CPU or other similar logic circuit and provided to the card reader or host device through a series of electronically generated bits positioned adjacent the active strip area or region 80.

Detailed Description Text (35):

FIG. 6 is a logic diagram of a program 100 for operating a communicating device. While the communicating device may operate in various manners without departing from the present invention, the program 100 includes verifying a PIN, incrementing the device pointer to the next transaction code, then transmitting the identification number, the transaction code and other optional information. Specifically, the PIN verification procedure may allow multiple attempts at entering the correct PIN, but deactivates the card if the correct PIN is not entered within x tries.

Detailed Description Text (36):

FIG. 7 is a logic diagram of a program 110 for operating a host device, such as a central or host computer having electronic communication with a plurality of communicating devices. This type of communication is typically discontinuous, meaning that communication sessions are of a finite duration and are separated by at least some pause or period of non-communication. As previously indicated, the host device will comprise a database containing a sequence of fields storing transaction specific codes. Each authorized communicating device is provided with a database or list of this same type contained in its computer memory, perhaps having a unique set of codes for each device. The same or different database may also contain information about the user, identification codes, device identification codes, and other verification information such as mother's maiden name and other information personal to the user. Such database may also contain historical information about the use of the authorized device or the preferences of the authorized user. All of this information may potentially be used by the computer to determine whether or not a communication is to be allowed.

Detailed Description Text (38):

If the identification number of the device is valid, then the host will locate its database of information and will begin to verify various information. This verification may proceed in any logical order, but is presented here as proceeding to determine whether the transactions specific code received from the communicating device is the same as the next expected transaction specific code in the host database. Without the programming or entry of a tolerance factor in the computer program, the transaction specific code transmitted and the next expected transaction specific code must be identical to allow the communication to proceed. However, it is believed to be beneficial in many applications to provide for some degree of tolerance. The term "tolerance" in the context of transaction specific codes preferably means that the transaction specific code received from the communicating device is identical to a transaction specific code stored in the host database within a range of fields sequentially subsequent to a previously received transaction specific code, i.e., a transaction specific code from a prior communication that was successful or authorized. Restated for the purposes of clarity, the host database pointer can be made forwardly tolerant by any number of fields. The extent of the forward tolerance will be specific to various applications depending upon a host of factors including the reliability of the data or communication, i.e., the nature and frequency of interruptions that are likely to occur even by authorized devices. In this manner the tolerance factor becomes a filter for distinguishing authorized communications from those that are not.

Detailed Description Text (39):

If the transaction specific code received is accepted, the pointer in the host database is reset at the transaction specific code received. The program may then look to other criteria in the transmission before authorizing the communication. As previously indicated these other criteria may include the specific location from which the communication is initiated, the frequency with which communications have been initiated, the nature or content of the communication itself, or other criteria

that would be application specific.

Detailed Description Text (40):

Depending upon the complexity of the communication or the degree of security desired, the communicating device may operate in a manner such that its database is self-incrementing upon successful entry of the personal identification code or upon successful communication with the host device. Alternatively, the database in the communicating device may be incremented only upon successful communication with the host device and/or only at the command of the host device. In the later situation, the host computer may send a new field location, or pointer, in the database rather than simply the next incremental location. Furthermore, in some applications where the communicating device has sufficient receiving and storing capabilities, the host computer may simply hand the communicating device its next transaction specific code necessary for communicating. Subsequent communications would then contain the new transaction specific code or password and any unauthorized communications would contain old or previously used codes. Therefore, while the role of the host computer is to verify or authenticate the communication, either the communicating device itself or the host computer may take control over the selection of the next transaction specific code, at least with a predetermined set of codes. In various embodiments, this control may be granted solely to the communicating device, solely to the host computer, or some combination thereof. An example of combined control over the transaction specific code sequence would be a communicating device programmed to increment after each communication, but subject to the host computer's periodic command to relocate the pointer in its database.

Detailed Description Text (41):

It should be recognized that one of the distinct advantages of the present invention is its adaptability to existing communication systems without significant modification of the communicating device or its peripherals. For example, in the application of cellular telephone communications, the modern cellular telephone is already equipped with a CPU having at least a minimum counting capability. A simple programming change in the cellular telephone would allow the counter's equivalent of a transaction specific code to be uploaded and transmitted along with the cellular telephone identification number and/or user identification number. Programming of the host device would proceed in accordance with the description of FIG. 7

Detailed Description Text (42):

Further, the program 110 of FIG. 7 may optionally include a subroutine 120 for automatically resynchronizing the pointer in the host database to correspond with the pointer in the database of the communicating device. The pointer is resynchronized by receiving and storing a sequence of r transaction specific codes from a sequence of r attempted communications. If the sequence of transaction specific codes matches any sequence of expected transaction specific codes in the host database, then the host pointer is reset to the transaction specific code following the last received transaction specific code.

Detailed Description Text (43):

When the present invention is applied to credit card use, the credit card itself must be modified to include a CPU, counter circuit or other logic circuit which can maintain, store, and update the transaction specific codes and a means for transmitting the transaction specific code to the credit card reader. The preferred method of achieving this is shown in FIGS. 3-5. While this is a significant modification of a credit card, the issuance of new cards made in accordance with FIGS. 3-5 is estimated to cost less than about \$2.00 per card and is deemed by the inventors to be a reasonable expense in light of the potential billion dollar savings in preventing a significant portion of credit card fraud. Modifications required of the host device are mere program changes which are believed to be relatively minor. Alternatively, various aspects of the present invention may be realized without modifying the actual credit card or other communicating devices by providing a separate, supplementary device, such as a hand held electronic device having a keypad, CPU, energy source and display, to be used in conjunction with the credit card. Such supplementary device would be used in an identical fashion as that described with reference to FIGS. 3-5, except that PIN input and transaction code generation and display are not performed within the card but in the supplementary device. The supplementary device may provide various modes of display or communication of the transaction specific code to the host device, including a visual display that is manually entered into the point-of-sale computer or card reader, an electronic signal, or other communication means known in the art.

Detailed Description Text (44):

In one alternative embodiment, upon detection of an inconsistent or out of sequence transaction specific code, the host computer does not need to immediately disallow the attempted communication but rather may prompt the communicating device for additional information which is known only to the authorized user. In this manner, inconvenience to authorized users may be minimized while achieving the objective of preventing use of cloned devices. The prompt for user specific information may include any information that the authorized user has previously made available to the host device or an individual entity operating the host device. For example, discussions with financial institutions or credit card organizations about an individuals credit may require the requestor to successfully give the maiden name of the user's mother. Furthermore, it should be recognized that this user specific information does not need to be the same type of information for each user.

Detailed Description Text (45):

While most of the foregoing discussion about the present invention has focused on the use of databases, lists and tables for storing transaction specific codes, it may be preferred in some applications having limited memory to provide an algorithm for calculating the next transaction specific code. In these applications, the pointer refers to the number of steps into the algorithm or the value input into the algorithm and the transaction specific code is the calculated output of the algorithm. The host device is provided with the same algorithm and compares the transaction specific code received from the communicating device with the next expected transaction specific code. The concept of "tolerance" described earlier may be incorporated either by setting an acceptable range of values for the transaction specific code (output of the algorithm) or the pointer itself (input to the algorithm), the later being the equivalent of back calculating the pointer and verifying that it is within the range of tolerance.

Current US Cross Reference Classification (2):

705/64

CLAIMS:

1. A method of preventing the use of a fraudulent device, comprising: (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with the transaction specific code indicated by the pointer in the first sequence, wherein the communication and transaction specific code do not comprise account numbers; (e) refusing communications having a transaction specific code that is different from the transaction specific code indicated by the pointer in the second communicating device; and (f) incrementing the pointers in a predetermined sequence within both the first and second sequences to the next transaction specific code in the absence of an interrogation transmission from the second communicating device.
2. The method of claim 1, wherein the first sequence of transaction codes is stored in a database.
3. The method of claim 1, wherein the first sequence of transaction codes is calculated.
4. The method of claim 3, wherein the second sequence of transaction specific codes is calculated.
6. The method of claim 1, wherein the first communicating device is a cellular telephone and the second communicating device is a cellular network.
15. A method of authenticating a communication comprising: (a) providing a first communicating device with a first identification code and a first sequence of transaction specific codes; (b) providing a host communicating device with the first identification code and the first sequence of transaction specific codes; (c) setting pointers in the first sequence of transaction specific codes of both the first communicating device and the host device at the same transaction specific code; (d) transmitting a communication from the first communicating device to the host communicating device along with the first identification code and the

transaction specific code associated with the pointer in the first sequence of transaction specific codes, wherein the first identification code and the transaction specific code do not comprise an account number; (e) disallowing communications transmitted with the first identification code that have a transaction specific code that is different from the transaction specific code associated with the pointer in the first sequence of transaction specific codes; and (f) incrementing the pointers in the first communicating device and the host communicating device in a common predetermined sequence in the absence of an interrogation transmission from the second communicating device.

16. The method of claim 15, wherein the first sequence of transaction codes is stored in a database.

17. The method of claim 15, wherein the first sequence of transaction codes is calculated.

18. The method of claim 17, wherein the second sequence of transaction specific codes is calculated.

19. A method of preventing the use of cloned device, comprising: (a) providing each of a plurality of communicating devices with a device identification code and an associated sequence of transaction specific codes; (b) providing a host communicating device with an identical copy of each of the device identification codes and the associated sequences of transaction specific codes; (c) setting pointers in the communicating device and the host device at the same transaction specific code in the sequence of transaction specific codes associated with each identification code; (d) transmitting a communication from the communicating device to the host communicating device along with the device identification code and the transaction specific code associated with the pointer in the sequence of transaction specific codes; (e) disallowing communications transmitted with the device identification code that have a transaction specific code that is different from the transaction specific code associated with the pointer in the sequence of transaction specific codes, wherein the identification codes and the transaction specific codes do not comprise an account number, and (f) incrementing the pointers in the communicating device and the host communicating device in a common predetermined sequence in the absence of an interrogation transmission from the second communicating device.

20. The method of claim 19, wherein the first sequence of transaction codes is stored in a database.

21. The method of claim 19, wherein the first sequence of transaction codes is calculated.

22. The method of claim 21, wherein the second sequence of transaction specific codes is calculated.

23. A method of communicating, comprising: (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with the transaction specific code adjacent the pointer in the first sequence without transmitting an account number; (e) refusing communications having a transaction specific code that is different from the transaction specific code adjacent the pointer in the second communicating device; and (f) incrementing the pointers in a predetermined sequence within both the first and second sequences to the next transaction specific code in the absence of an interrogation transmission from the second communicating device.

24. The method of claim 23, wherein the predetermined sequence for incrementing the pointer is the same order as the first and second sequences of transaction specific codes.

25. The method of claim 23, wherein the communication is a credit card transaction, and wherein the communication does not include an account number for the credit card.

31. The method of claim 23, further comprising the step of: after refusing a communication, resetting the pointer in the host database upon receiving a series of attempted communications having a series of transaction specific codes that match a portion of the database.

32. The method of claim 23, wherein the pointer in both databases is directed to the same field containing the same transaction specific code prior to the first communication.

34. The method of claim 23, further comprising the step of resetting the pointer in the host communicating device upon receiving a series of attempted communications having transaction specific codes that match a portion of the database.

35. A method of communicating, comprising: (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with the transaction specific code adjacent the pointer in the first sequence and without transmitting an account number; (e) refusing communications having a transaction specific code that is not identical to a transaction specific code in the second communicating device within a predetermined range of fields in the sequence subsequent to the pointer in the second communicating device; and (f) incrementing the pointers in a predetermined sequence within both the first and second sequences to the next transaction specific code in the absence of an interrogation transmission from the second communicating device.

36. The method of claim 35, further comprising the step of resetting the pointer in the second communicating device to the field having a transaction specific code identical to the received transaction specific code if the field is within the predetermined range of fields subsequent to the pointer.

#### ABSTRACT:

The present invention provides a method and apparatus for identifying and minimizing the use of cloned communicating devices which communicate with a host device. The method requires that the communicating devices send a transaction specific code and an identification code, along with each communication wherein the transaction specific code changes between each communication. One communicating device, either the authentic device or a fraudulent device might communicate with the host successfully any number of times. However, when a second devices attempts communication whether that device is the authorized device or fraudulent device, the host device will receive a transaction specific code which is inconsistent or out of sequence with that expected by the host. The host device will preferably disallow all further communications involving the particular identification code until the

authorized user can be contacted and the transaction specific code reset or even a new set of transaction specific codes are provided. Alternatively, upon detection of the inconsistent transaction specific code, the host computer may prompt the user for information specific to the authorized user that is not stored in the communicating device and would not be readily available to the clone device or the user of the clone device.

TITLE: Method and apparatus for securing digital communications

Abstract Text (1):

The present invention provides a method and apparatus for identifying and minimizing the use of cloned communicating devices which communicate with a host device. The method requires that the communicating devices send a transaction specific code and an identification code, along with each communication wherein the transaction specific code changes between each communication. One communicating device, either the authentic device or a fraudulent device might communicate with the host successfully any number of times. However, when a second devices attempts communication whether that device is the authorized device or fraudulent device, the host device will receive a transaction specific code which is inconsistent or out of sequence with that expected by the host. The host device will preferably disallow all further communications involving the particular identification code until the authorized user can be contacted and the transaction specific code reset or even a new set of transaction specific codes are provided. Alternatively, upon detection of the inconsistent transaction specific code, the host computer may prompt the user for information specific to the authorized user that is not stored in the communicating device and would not be readily available to the clone device or the user of the clone device.

Brief Summary Text (3):

The present invention relates to the security of communications, and more particularly to a method and apparatus for combating the use of cloned, fraudulent or unauthorized communicating devices, such as cellular telephones, credit cards and computer terminals.

Brief Summary Text (5):

Communication signals are used widely in many different or interrelated fields, such as credit card authorization systems, cellular telephone and radio communications, satellite transmissions, telephone calls, computer networks and modem connections, automated teller machine transmissions, direct broadcast television, garage door openers, automobile remote devices and the like. While each of these fields may have different communication protocols, performance objectives and technical constraints, each of the fields have at least some concern for the security of the communication. Specific security concerns may deal with the content of the communication itself (often protected by encryption methods), the integrity of the communication (often protected by error-checking and anti-virus software), and authorized access to the communication (often protected by account codes and passwords).

Brief Summary Text (6):

Unauthorized access to communications and communicating devices has become a problem in many of the fields mentioned. Computer networks have been broken into by determining authorized account codes and passwords, thereby gaining access to proprietary information or computing capabilities Credit card transactions may be charged by an unauthorized person by merely possessing a lost or stolen card. Cellular telephones may be duplicated or cloned to produce a large number of fraudulent telephones having the same account codes and personal identification codes as a lost or stolen authentic cellular telephone. Attempts to combat these unauthorized communications has taken many forms.

Brief Summary Text (8):

For example, a serious problem in existing cellular telephone systems may be referred to as the "false mobile station" syndrome. It is presently possible to copy the entire memory contents of a mobile station and to use that information to manufacture clones which can demand and receive service from the network. Cellular phones may be cloned by reading the entire memory contents of the phone, including its identification codes, secret keys, internally stored personal identification codes, signatures, etc., and writing the same codes into any number of similar "clone" phones. The cloning procedure can become quite sophisticated and may include software modifications which replace physically stored information with electronically stored information so that a number of stored mobile station identities may be cyclically rotated within one fraudulent mobile station and used to imitate several authentic mobile stations.

Brief Summary Text (9):

Similar breaches of communications have occurred in financial transactions involving credit cards. Typically, the information on a lost or stolen credit card can be electronically read and duplicated on any number of credit cards. The cards are then distributed and used until either the credit limit of the card is surpassed or the card is reported stolen or lost to the credit card company. Significant actual losses are experienced each year due to the use of such "cloned" credit cards.

Brief Summary Text (10):

Many communication systems, including cellular telephone networks and credit card authentication or authorization systems, comprise a vast number of distributed communicating devices (i.e., mobile cellular phones or credit cards and credit card readers) that transmit data to a central computer system in charge of determining whether or not to allow the communication to go through. The central computer system may execute an authorization algorithm to determine if the credit card has a valid account or identification number, if there is an available balance of credit and, perhaps, if a valid personal identification number has been given or entered. However, sophisticated thieves have been able to duplicate the credit card with valid identification numbers and determine even the personal identification number.

Brief Summary Text (11):

Similarly, computer network communications or computer-to-computer communications may include files that are locked, password protected, zipped and/or encrypted for various reasons, including the security of the content of the communication. Password protection provides a limited degree of security, primarily protecting a communication from being accessed by persons who casually encounter the file, but this security can still be violated. Encryption is perhaps the most secure means for preventing outsiders from obtaining the content of the communication and, therefore, is in widespread use by banks and other financial institutions throughout the world for many or all of their electronic transactions.

Brief Summary Text (15):

The present invention provides a method of authenticating a communication, comprising (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with a transaction specific code from the first sequence; (e) refusing communications having a transaction specific code that is different from the transaction specific code expected by the second communicating device; and (f) incrementing the pointers in both the first and second communicating devices. The first and second sequences of transaction codes may be stored in a database or calculated according to various algorithms.

Brief Summary Text (16):

The first and second communicating devices may take on various forms and functions. For example, the first communicating device may be a credit card and the second communicating device a central clearinghouse; the first communicating device may be a cellular telephone and the second communicating device a cellular network; the first communicating device may be a garage door remote and the second communicating device a garage door opener; the first communicating device may be an automobile remote unlock device and the second communicating device an automobile remote unlock

device receiver; the first communicating device may be a computer and the second communicating device another computer; and the first communicating device may be a direct broadcast television system and the second communicating device a television receiver. It should also be recognized that the communication may proceed through transmissions selected from electrical, radio and optical.

Brief Summary Text (17):

The invention also provides a method of authenticating a communication, comprising: (a) providing a first communicating device with a first identification code and a first sequence of transaction specific codes; (b) providing a host communicating device with the first identification code and the first sequence of transaction specific codes; (c) setting pointers in the first sequence of transaction specific codes of both the first communicating device and the host device at the same transaction specific code; (d) transmitting a communication from the first communicating device to the host communicating device along with the first identification code and the transaction specific code associated with the pointer in the first sequence of transaction specific codes; (e) disallowing communications transmitted with the first identification code that have a transaction specific code that is different from the transaction specific code associated with the pointer in the first sequence of transaction specific codes; and (f) incrementing the pointers in the first communicating device and the host communicating device.

Brief Summary Text (18):

The invention further provides a method of authenticating a communication, comprising: (a) providing each of a plurality of communicating devices with a device identification code and an associated sequence of transaction specific codes; (b) providing a host communicating device with an identical copy of each of the device identification codes and the associated sequences of transaction specific codes; (c) setting pointers in the communicating device and the host device at the same transaction specific code in the sequence of transaction specific codes associated with each identification code; (d) transmitting a communication from one of the communicating devices to the host communicating device along with the device identification code and the transaction specific code associated with the pointer in the sequence of transaction specific codes; (e) disallowing communications transmitted with the device identification code that have a transaction specific code that is different from the transaction specific code associated with the pointer in the sequence of transaction specific codes; and (f) incrementing the pointers in the communicating device and the host communicating device.

Brief Summary Text (19):

The invention also provides a method of detecting the existence of two or more communicating devices having the same identification code comprising the steps of: (a) transmitting an identification code and a transaction specific code from a first communicating device to a host device; and (b) comparing the transaction specific code received by the host device with a next expected transaction specific code for a communicating device having the particular identification code.

Brief Summary Text (20):

Further, the invention provides a method of communicating between a communicating device and a host device, comprising the step of transmitting an identification code and a transaction specific code to the host device wherein the identification code is unique to the communicating device and the transaction specific codes are predetermined and known by the communicating device and the host device for the purpose of allowing the host device to detect the usage of a fraudulent communicating device having the same identification code. The method may also comprise changing the transaction specific code for subsequent attempted communications. The method may further comprise disallowing communications having an improper transaction specific code.

Brief Summary Text (21):

The invention additionally provides a method of disallowing communications initiated by fraudulent communicating devices comprising (a) receiving an identification code and a transaction specific code from a communicating device; (b) searching a list of transaction specific codes in the host device; and (c) having a predetermined sequence of transaction specific codes for the next expected transaction specific code from a device having the received identification code.

Brief Summary Text (22):

Finally, the invention provides a method of resynchronizing the next expected

transaction specific code between communicating devices by matching a pattern of transaction specific codes in the communicating device with a pattern of transaction specific codes in the host device.

Drawing Description Text (5):

FIG. 3 is a schematic diagram of a simple credit card apparatus which includes a magnetic strip or other communication media.

Drawing Description Text (6):

Drawing Description Text (7):

FIG. 5 is a partial cross-sectional view of the credit card of FIG. 4.

Detailed Description Text (2):

The present invention provides a method and apparatus for identifying and approving authentic communications. Such method and apparatus are important for preventing unauthorized communications through various communication media, including electronic, audible, visual or the like. Perhaps the most widely used media for communications in business and personal applications include electronic and radio frequency communications such as those involving computer to computer transfers, credit card authorization and approval, cellular telephone calls and data transmissions, satellite broadcasts, automated teller machine transactions, and other electronic communications. For various reasons, it is frequently desirable or necessary for access to these communications to be restricted to authorized persons, authorized equipment, authorized locations, and the like. While the set of criteria necessary to authenticate a transmission or communication may be short and simple or long and complicated, the present invention proposes a simple, yet effective, method for preventing unauthorized communications. More particularly, the present invention prevents the successful use of multiple cloned or otherwise fraudulent devices, and limits the use of even a single cloned or otherwise fraudulent device to the time interval between the "cloning" event and the next authentic communication. Such time interval may be as long as several days (for example an infrequently used credit card) or as short as fractions of a second (for example in electronic financial transactions between institutions).

Detailed Description Text (3):

In one aspect of the invention, a method is provided for preventing the cloning and fraudulent use of various authentic communicating devices. Attempts to increase the complexity of the communicating device or the difficulty of successfully duplicating the device have met with limited success, because once the device has been successfully cloned, unauthorized communications may be accomplished. The methods of the present invention do not depend upon the complexity of the physical communicating device or the magnitude of possible security codes or keys, but rather, the present invention provides for transmitting a transaction specific code along with identification codes and the communication itself in accordance with a predetermined set of transaction codes known to a central authorizing device or host. These codes may take various forms including, but not limited to, numeric, alphabetic, alpha numeric and the like and may be transmitted through various media including, but not limited to, digital or analog electronic signals, radio waves, light waves, chemical or other optical means, other wave forms, and the like. The transaction specific code may be as simple as a sequential set of algorithmically generated numbers, such as 1 through 100, or some random set of codes predetermined and stored in both the communicating device and the host communicating device.

Detailed Description Text (4):

The invention operates on the principal that when an authorized communicating device transmits a series of communications, with each communication accompanied by a transaction specific code, the host or receiving device, such as a computer, will expect to receive the transaction specific codes in a particular, predetermined sequence. So long as subsequent communications contain a transaction specific code consistent with the existence of only one authorized communicating device having a given identification code, then the communication may be allowed or authorized. In the event that communications are initiated containing transaction specific codes which indicate the presence of duplicate communicating devices, then the communications will be disallowed. The methods just described do not address or prevent the physical cloning of the communicating device, but rather prevent the successful use of cloned devices over a period of time or the successful access to a communication over a period of time.

Detailed Description Text (5):

In another aspect of the invention, subsequent communications may be re-initiated by resetting the pointer at a different point in the sequence of predetermined codes in the authorized communicating device. In this case, the host device must also be informed of the reset point in order maintain synchronization. Alternatively, the communicating device and host device may be provided with a new set of transactions specific codes. The provision of new codes may be accomplished in any manner, manual or automatic, but automatic or periodic updating of codes may require modification of existing communicating devices which do not have sufficient receiving and storing capabilities.

Detailed Description Text (6):

Typical cloning patterns, such as those experienced in the credit card and cellular telephone markets, involve the loss or theft of a single authorized communicating device, i.e., the physical credit card or cellular telephone, which is then duplicated to provide a large number of fraudulent devices which operate identical to the authorized communicating device. In accordance with the prior art, the successfully cloned, yet fraudulent, devices were allowed to communicate successfully leading to losses of millions or billions of dollars. As indicated above, the methods of the present invention do not rely upon device designs which are presently difficult to copy or clone, but provides a method by which the use of two or more devices, such as the authorized device and one fraudulent device or multiple fraudulent devices, is identified by the host device upon receiving a transaction specific code which is inconsistent with the predetermined set of codes.

Detailed Description Text (7):

In one aspect of the invention, the degree of inconsistency in the transaction specific codes can be modified or tailored to a specific application. For example, a transaction specific code may be sufficient to allow a communication to be authorized so long as it falls within a particular range of transaction specific codes expected by the host. More particularly, in the situation where the transaction specific codes are a sequence of numbers from 1 through 100 listed in numerical order, a sequence of communications would be expected to include transaction specific codes that fall in a sequence, such as 1, 2, 3, 4, 5, etc. However, for specific applications such as credit card use, it may be acceptable to allow or authorize communications containing transaction specific codes that are within a range of codes next expected by the host. Therefore, if the host was expecting to receive transaction specific codes of 1, 2, 3, 4, 5, 6, 7, 8, etc. over a series of communications, then a series of communications containing transaction specific codes of 1, 2, 4, 5, 7, 8 would be allowed if the host device were programmed with a tolerance of two codes. It is also anticipated that the host computer may take additional action if the transaction code tolerance is required too frequently.

Detailed Description Text (8):

It should be recognized that the set of codes to be transmitted by the authorized communicating device and stored in a database within the host device may comprise a mere list or database of transaction specific codes established in a given order. While the fields of the database are maintained in a certain sequence, the transaction specific codes within those fields may vary in any manner. Therefore, the database programmed into the communicating device and the host device may have a database segment containing the numerical transaction specific codes of 54, 86, 32, 64, 35, and 97. To an outside observer or someone intercepting these codes, the code would appear to be random or at least undeterminable. However, the host device knows what the next expected transaction specific code is to be, i.e., if the previous transaction specific code was 86, then the next expected transaction specific code is 32, but transaction specific code of 64 would be accepted if the tolerance were set at two fields. This ability allows the host computer to determine whether or not the communication is authentic. In this context, the concept of tolerance no longer implies that the transaction specific code has a numerical value within a certain range, but rather that the transaction specific code may be found within a range of fields within the database forwardly adjacent to a field containing the next expected code. The ability of the database to contain any number of transaction specific codes of any length or type of signal vastly increases the difficulty of predicting the next transaction specific code. However, even in the simplest of embodiments, where the transaction specific codes comprise a sequence of numbers in numerical order, the invention still prevents widespread cloning in the manner

described above. Furthermore, a simple embodiment of the present invention allows the host computer to dispense with an actual database but rather comprise a single data register or memory location for storing either the last transaction specific code, the next expected transaction specific code, or some equivalent means of tracking used or soon to be used codes.

Detailed Description Text (9):

While the foregoing discussion has dealt primarily with detecting unauthorized communicating devices, the present invention may also include the ability to detect unauthorized users. In many applications, including credit card authorization and approval and cellular telephone communications, it is frequently desirable to verify that the communication is being initiated by an authorized user. The inclusion of a user authorization system is beneficial for reducing the use of the authentic communicating device when it has been stolen or lost. Losses due to the use of lost or stolen communicating devices is also very significant, but is inherently limited to the capacity of via the authorized communicating device itself, i.e., one communication at a time, a credit limit, etc. Furthermore, the use of lost or stolen communicating devices by unauthorized users may be restricted by the use of user specific codes, such as a personal identification number (PIN), finger print, password, voice command and the like.

Detailed Description Text (10):

In another aspect of the invention, the host device and/or the communicating device may be programmed to verify the identity and authenticity of the device alone or in combination with the user. In one example, the host computer may first verify that the communication is being initiated from an authorized communicating device, then prompt the user to enter a personal identification code (PIN) indicating that the user is also authorized. Only upon satisfaction of these two criteria is the communication be allowed to proceed. It should be recognized that the host device could be programmed to verify these two codes, or other additional codes and authorizations, in any order. In another example, the communicating device itself may require the successful input of a personal identification code prior to enabling or energizing the transaction specific code, any portion of the device identification code or even some portion of the communication itself.

Detailed Description Text (11):

A still further aspect of the invention provides for automatic re-synchronization of the transaction specific codes following one or more unauthorized communications. Re-synchronization methods according to the present invention may be achieved by programming the host device to reset the pointer in a database of transaction specific codes for a particular identification code upon receiving a series of attempted communications having a series of transaction specific codes that match a portion of the database. For example, after receiving an attempted communication having a transaction specific code that is not the next expected transaction specific code or within the range of tolerance, no further communications using the same identification code can proceed until the transaction specific codes of the communicating device and the host are re-synchronized. If the host device is programmed to allow re-synchronization after receiving three transaction specific codes (i.e., 12, 13, 14) that match a portion of the host database (i.e., 10, 11, 12, 13, 14, 15, 16, etc.) for the given identification code, then the pointer in the host database is reset for the next transaction specific code (i.e., 15) in the database. Subsequent communications may proceed in accordance with the aforementioned methods. It may be beneficial to a separate range of tolerance for re-synchronization in order to prevent re-synchronization at a dramatically different point in the sequence of transaction specific codes.

Detailed Description Text (12):

Another aspect of the invention provides for periodically incrementing, or otherwise moving, the pointers in the transaction specific codes in both the communicating device and the host device. The periodic movement of the pointer is advantageous because it effectively shortens the time period or "window of opportunity" in which a cloned device having a full and correct set of transaction specific codes may operate. For example, if an authentic communicating device is infrequently used, a cloned device may initiate successful communications until such time as the authentic communicating device is used again. However, if the authentic communicating device and the host device are designed or programmed for periodically moving their database pointers, in accordance with a predetermined algorithm, then the cloned device may initiate successful communications only until the next movement of the database pointers. Specifically, the database pointers may be

incremented by one or more fields after specific time intervals, i.e., ten minutes, an hour, a day, etc.

Detailed Description Text (13):

FIG. 1 is a schematic diagram of an identification and authorization system 10 in accordance with the present invention. A communicating device 12 generates and transmits a communication 16 to a host device 14, wherein the communication 16 comprises an identification code 18, a transaction specific code 20 and the content 22 of the communication itself. Note that both the communicating device 12 and the host device 14 contain similar databases, lists or tables 24, 26, respectively, having a plurality of fields 28, 30 containing the same transaction specific codes in the same sequence. Prior to the first communication, a pointer in both databases is directed to the same field containing the same transaction specific code.

Detailed Description Text (14):

It should be recognized that the host device 14, or perhaps even communicating devices which are capable of transmitting or receiving communications from or to a plurality of other devices, may have a plurality of n lists of transaction specific codes, where n is the number of authorized identification codes, such as the identification code 32 having the list 26. Each of the n lists in the host device 14 will have a pointer, such as pointer 34, which indicates the next expected field in the sequence of m fields in the list or database 26 which, in turn, contains the next expected transaction specific code (i.e., TS Code=ABC123). Similarly, the database 24 of the communicating device 12 has a pointer 36 which indicates the next transaction specific code (i.e., ABC123) to be transmitted along with the identification code 38. Upon receiving the communication 16, the host device 14 determines the identification code 18 and looks for the identification code among the n authorized identification codes. Then the host device 14 compares the transaction specific code 20 received from the communicating device 12 with the transaction specific code 30 indicated by the pointer 34.

Detailed Description Text (15):

During subsequent communications, the transmission from the communicating device 12 will contain subsequent transaction specific codes 28 from the database 24. Errant or failed communications may lead to the pointer 36 of the communicating device 12 incrementing to the next field in the database 24 without the communication ever being received by the host device 14 and, consequently, without the database 26 of the host device 14 ever being incremented. This and other similar situations represent a benefit of using the tolerance feature described above. If the host device 14 receives a transaction specific code 20 falling in the database within a reasonable range of fields, typically only fields in the forward direction, then the communication is allowed to proceed. For example, if the tolerance is set to three fields 40 and the pointer 34 is set at the field containing "ABC123", then the host device 14 may authorize communications having an identification code 32 and a transaction specific code of "ABD123", "MOON" or "FRED", but not "DOG" (since it is not in a forwardly directed field) or "64" (since it is outside the tolerance range of 3). In this example, if the communication was authorized on the basis of a transaction specific code of "FRED", then the database pointer 34 in the host device 14 would preferably be reset to a next expected transaction specific code of "64" which matches that of the communicating device 12.

Detailed Description Text (16):

It should be recognized that communications having acceptable identification codes and transaction specific codes may be further subject to verification of other conditions, such as a personal identification number (PIN) and the like. Examples of other conditions or criteria useful for determining whether or not to authorize a particular communication include the location from which the communication is initiated, the frequency with which communications occur, the type of communication being attempted, the content of the communication itself, and discrepancies between time and space which indicate the unlikely use of a single device suggesting cloning. Other useful criteria will become apparent in specific applications.

Detailed Description Text (17):

As shown in FIG. 1, the communicating device 12 preferably includes a member 42 for providing the content 22 of the communication 16 to a transmitter 44. The actual transmission may be initiated in any number of manners, but specifically may be initiated with a "send" button 46, such as that on a cellular telephone or by the act of swiping a credit card. The host device 14 preferably includes a receiver 48 and a central processing unit (CPU) 50. The CPU 50 is provided with the

communication 16 from the receiver 48 and executes a series of steps in order to authenticate the communication.

Detailed Description Text (18):

FIG. 2 is a conceptual diagram which is useful for arriving at a full understanding of the one aspect of the present invention. The diagram of FIG. 2 presents a set of keys on a ring 52 and a set of locks 54 in a door 56 which operate analogous to the present invention. The key ring 52 (communicating device) includes a fob 58 (identification code) and a plurality of keys 60 (transaction specific codes). The door 56 (host device) includes a plurality of locks 62 (expected transaction specific codes) for each fob (identification code) which can only be unlocked by using a specific key (transmitted transaction specific code). The locks 62 (transaction specific codes) in the door (host) are rotated (incremented) in the direction of arrow 64 by a mechanism each time the door is unlocked. Similarly, the keys (transaction specific codes) on the key ring 52 are rotated (incremented) each time a key is used.

Detailed Description Text (19):

The door and key ring are initially used as shown, with the key a and lock A ready for the first unlocking of the door (communication). When key a unlocks the door with lock A, then the door is open for a transaction to pass therethrough. Note that the transaction does not need to have any actual connection with the key nor the lock. Anything may move through the doorway once the door is unlocked.

Detailed Description Text (20):

When the transaction is completed, the door is closed, the next lock in the rotation is moved into place and the keys are rotated around the ring in preparation for the next unlocking. In this case, the key b is positioned as the next key to be used and the lock B is positioned as the next operating lock in the door.

Detailed Description Text (21):

To enable the next transaction, key b is used with lock B. The door is unlocked and open for the transaction as before. When this second transaction is completed, the door is closed and both the keys are rotated to key c and the locks are rotated to lock C. Note that this transaction system operates with synchronous rotation of the keys and locks. Only one key on the ring will unlock the door for any specific transaction, thereby providing much greater security than a more complex key.

Detailed Description Text (25):

This mechanical analogy illustrates four features of sequential synchronized keys: (1) it is difficult to guess the next key; (2) the keys are not specifically related to the content of the transaction; (3) there are various ways of guarding the lock from tampering; and (4) there are various ways of guarding the keys from duplication.

Detailed Description Text (26):

FIG. 3 is a schematic diagram of a credit card apparatus 70 which includes a body member 71, perhaps made of plastic, and a magnetic strip 72, such as iron oxide, or other communication media which is preferably enabled upon successful entry of a predetermined personal identification number. A personal identification number may be entered through a dedicated or multipurpose key pad 74 made according to various designs known in the art. The complexity of the keypad 74 may vary from a full ten digit keypad or a full alphabetic keyboard to a much simpler keypad containing, for example, three or four buttons that are color coded. Regardless of the complexity or number of keys, the personal identification number may contain as many digits as desirable.

Detailed Description Text (27):

In a further aspect of the invention, the successful entry of a personal identification number or code may also result in the generation of a visual indicator on a display 76 that signifies successful entry. Such a visual indicator would be useful in applications where the initiation of the communication is attended by a representative interested in the proper authorization of the communication, for example, a sales clerk in a retail outlet which either does not have electronic authorization equipment or such equipment is presently inoperable. A visual indicator may also be useful in situations where electronic verification equipment is available, but the sales representative is available to monitor the number of unsuccessful attempts at entering the personal identification number. In any of these circumstances, the sales clerk could require the visual indicator prior

to proceeding with the transaction or communication.

Detailed Description Text (28):

Still referring to FIG. 2, the card 70 of the present invention makes use of conventional magnetic media supplemented with at least one electronically generated bit of information. This electronically generated bit may occur anywhere in the magnetic strip 72, including the region 78 containing a cyclic redundancy check or other verification code such as a check bit system, the region 80 containing an identification number, the region 82 containing the transaction specific code, or any other region. Further, the electronically generated bit may comprise its own region 84, perhaps indicating to the host through a card reader that the user is authorized, i.e., has successfully entered the personal identification number.

Detailed Description Text (29):

Operation of the card 70 is facilitated by an energy source 86, such as a lithium battery or a solar cell. The energy source 86 must provide sufficient power for any device on the card, such as the display 76, an electronically generated bit (shown here as located in the region 82), the keypad 74 and a CPU 88. The CPU 88 may be entirely embedded within the card 70 or located as desired for protection of the CPU or ease of manufacture. The CPU 88 is responsible for verifying correct PIN entry from the keypad 74, providing a signal to display 76, controlling the electronically generated bit(s) (shown here in region 82), and other various functions that are necessary or desirable to the function of the card. Further, the card 70 may comprise a multifunction device such as a calculator, etc.

Detailed Description Text (30):

FIG. 4 is a cross-sectional view of the credit card 70 of FIG. 3. Specifically, an electronically generated bit is produced by a small wire 90 disposed across the path of the magnetic strip 72. Each wire 90 is coupled to the energy source or battery 86 which, under control of the CPU 88, will provide electrical current to the wire 90 for a predetermined time period. The amount of current passing through the wire 90 is preferably no more than that sufficient to induce a magnetic flux at the surface of the credit card 70 which is equivalent to, or at least detectable by a card reader 92 as equivalent to, a zero (0) or a one (1) in the magnetic strip. When the electronically generated bit is inactive (not energized), reading the magnetic strip will indicate that a bit is missing (i.e., neither a zero or one are detected) and that the card is damaged, ineffective or unauthorized.

Detailed Description Text (31):

In another aspect of the invention, this electronically generated bit or any number of electronically generated bits may be provided to indicate other information about the use of the card, such as an excessive number of attempts to enter the personal identification code. Other uses for additional electronically generated bits will become apparent in particular applications.

Detailed Description Text (32):

The present invention encompasses the use of any number of electronically generated bits or conductive wires 90. However, in order to merely energize the card and complete a coherent transmission, only a single wire is necessary. However, in other embodiments, it is anticipated that multiple wires will be desirable. For example, transaction specific codes may be provided by the internal CPU or other similar logic circuit and provided to the card reader or host device through a series of electronically generated bits positioned adjacent the active strip area or region 80.

Detailed Description Text (34):

FIG. 5 is a partial cross-sectional view of the credit card of FIG. 4. A portion of the magnetic strip region 80 is shown made of a magnetic media, such as iron oxide, which form a magnetic field 95 between a north pole 94 and an adjacent south pole 96, to indicate a single bit of information containing a "1". Immediately adjacent or abutting the region 80 is a region 82 having at least one electronically generated bit produced by the conducting wire 90 disposed in the card. The wire 90 may be round or square, but is preferably square to maximize the magnetic field 98 generated above the card surface in accordance with known principles of induction. The "right-hand rule" of induction requires that an electrical current flowing through the wire 90 in the direction out of the page will cause a magnetic flux 98 in a direction counter-clockwise on the page. The magnetic field 98 can be made similar in strength to the magnetic field 95 by adjusting the amount of electrical current in the wire 90. Additionally, each wire 90 shown in FIGS. 4 and 5 may be

replaced by multiple windings of a smaller wire in order to obtain greater magnetic flux with the same amount of current. These and other expedient modifications will be apparent to one of ordinary skill in the art and are deemed to be within the scope of the present invention.

Detailed Description Text (35):

FIG. 6 is a logic diagram of a program 100 for operating a communicating device. While the communicating device may operate in various manners without departing from the present invention, the program 100 includes verifying a PIN, incrementing the device pointer to the next transaction code, then transmitting the identification number, the transaction code and other optional information. Specifically, the PIN verification procedure may allow multiple attempts at entering the correct PIN, but deactivates the card if the correct PIN is not entered within x tries.

Detailed Description Text (36):

FIG. 7 is a logic diagram of a program 110 for operating a host device, such as a central or host computer having electronic communication with a plurality of communicating devices. This type of communication is typically discontinuous, meaning that communication sessions are of a finite duration and are separated by at least some pause or period of non-communication. As previously indicated, the host device will comprise a database containing a sequence of fields storing transaction specific codes. Each authorized communicating device is provided with a database or list of this same type contained in its computer memory, perhaps having a unique set of codes for each device. The same or different database may also contain information about the user, identification codes, device identification codes, and other verification information such as mother's maiden name and other information personal to the user. Such database may also contain historical information about the use of the authorized device or the preferences of the authorized user. All of this information may potentially be used by the computer to determine whether or not a communication is to be allowed.

Detailed Description Text (38):

If the identification number of the device is valid, then the host will locate its database of information and will begin to verify various information. This verification may proceed in any logical order, but is presented here as proceeding to determine whether the transactions specific code received from the communicating device is the same as the next expected transaction specific code in the host database. Without the programming or entry of a tolerance factor in the computer program, the transaction specific code transmitted and the next expected transaction specific code must be identical to allow the communication to proceed. However, it is believed to be beneficial in many applications to provide for some degree of tolerance. The term "tolerance" in the context of transaction specific codes preferably means that the transaction specific code received from the communicating device is identical to a transaction specific code stored in the host database within a range of fields sequentially subsequent to a previously received transaction specific code, i.e., a transaction specific code from a prior communication that was successful or authorized. Restated for the purposes of clarity, the host database pointer can be made forwardly tolerant by any number of fields. The extent of the forward tolerance will be specific to various applications depending upon a host of factors including the reliability of the data or communication, i.e., the nature and frequency of interruptions that are likely to occur even by authorized devices. In this manner the tolerance factor becomes a filter for distinguishing authorized communications from those that are not.

Detailed Description Text (39):

If the transaction specific code received is accepted, the pointer in the host database is reset at the transaction specific code received. The program may then look to other criteria in the transmission before authorizing the communication. As previously indicated these other criteria may include the specific location from which the communication is initiated, the frequency with which communications have been initiated, the nature or content of the communication itself, or other criteria that would be application specific.

Detailed Description Text (40):

Depending upon the complexity of the communication or the degree of security desired, the communicating device may operate in a manner such that its database is self-incrementing upon successful entry of the personal identification code or upon successful communication with the host device. Alternatively, the database in the communicating device may be incremented only upon successful communication with the

host device and/or only at the command of the host device. In the later situation, the host computer may send a new field location, or pointer, in the database rather than simply the next incremental location. Furthermore, in some applications where the communicating device has sufficient receiving and storing capabilities, the host computer may simply hand the communicating device its next transaction specific code necessary for communicating. Subsequent communications would then contain the new transaction specific code or password and any unauthorized communications would contain old or previously used codes. Therefore, while the role of the host computer is to verify or authenticate the communication, either the communicating device itself or the host computer may take control over the selection of the next transaction specific code, at least with a predetermined set of codes. In various embodiments, this control may be granted solely to the communicating device, solely to the host computer, or some combination thereof. An example of combined control over the transaction specific code sequence would be a communicating device programmed to increment after each communication, but subject to the host computer's periodic command to relocate the pointer in its database.

Detailed Description Text (41):

It should be recognized that one of the distinct advantages of the present invention is its adaptability to existing communication systems without significant modification of the communicating device or its peripherals. For example, in the application of cellular telephone communications, the modern cellular telephone is already equipped with a CPU having at least a minimum counting capability. A simple programming change in the cellular telephone would allow the counter's equivalent of a transaction specific code to be uploaded and transmitted along with the cellular telephone identification number and/or user identification number. Programming of the host device would proceed in accordance with the description of FIG. 7

Detailed Description Text (42):

Further, the program 110 of FIG. 7 may optionally include a subroutine 120 for automatically resynchronizing the pointer in the host database to correspond with the pointer in the database of the communicating device. The pointer is resynchronized by receiving and storing a sequence of r transaction specific codes from a sequence of r attempted communications. If the sequence of transaction specific codes matches any sequence of expected transaction specific codes in the host database, then the host pointer is reset to the transaction specific code following the last received transaction specific code.

Detailed Description Text (43):

When the present invention is applied to credit card use, the credit card itself must be modified to include a CPU, counter circuit or other logic circuit which can maintain, store, and update the transaction specific codes and a means for transmitting the transaction specific code to the credit card reader. The preferred method of achieving this is shown in FIGS. 3-5. While this is a significant modification of a credit card, the issuance of new cards made in accordance with FIGS. 3-5 is estimated to cost less than about \$2.00 per card and is deemed by the inventors to be a reasonable expense in light of the potential billion dollar savings in preventing a significant portion of credit card fraud. Modifications required of the host device are mere program changes which are believed to be relatively minor. Alternatively, various aspects of the present invention may be realized without modifying the actual credit card or other communicating devices by providing a separate, supplementary device, such as a hand held electronic device having a keypad, CPU, energy source and display, to be used in conjunction with the credit card. Such supplementary device would be used in an identical fashion as that described with reference to FIGS. 3-5, except that PIN input and transaction code generation and display are not performed within the card but in the supplementary device. The supplementary device may provide various modes of display or communication of the transaction specific code to the host device, including a visual display that is manually entered into the point-of-sale computer or card reader, an electronic signal, or other communication means known in the art.

Detailed Description Text (44):

In one alternative embodiment, upon detection of an inconsistent or out of sequence transaction specific code, the host computer does not need to immediately disallow the attempted communication but rather may prompt the communicating device for additional information which is known only to the authorized user. In this manner, inconvenience to authorized users may be minimized while achieving the objective of preventing use of cloned devices. The prompt for user specific information may include any information that the authorized user has previously made available to

the host device or an individual entity operating the host device. For example, discussions with financial institutions or credit card organizations about an individuals credit may require the requestor to successfully give the maiden name of the user's mother. Furthermore, it should be recognized that this user specific information does not need to be the same type of information for each user.

Detailed Description Text (45):

While most of the foregoing discussion about the present invention has focused on the use of databases, lists and tables for storing transaction specific codes, it may be preferred in some applications having limited memory to provide an algorithm for calculating the next transaction specific code. In these applications, the pointer refers to the number of steps into the algorithm or the value input into the algorithm and the transaction specific code is the calculated output of the algorithm. The host device is provided with the same algorithm and compares the transaction specific code received from the communicating device with the next expected transaction specific code. The concept of "tolerance" described earlier may be incorporated either by setting an acceptable range of values for the transaction specific code (output of the algorithm) or the pointer itself (input to the algorithm), the later being the equivalent of back calculating the pointer and verifying that it is within the range of tolerance.

Current US Cross Reference Classification (2):  
705/64

CLAIMS:

1. A method of preventing the use of a fraudulent device, comprising: (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with the transaction specific code indicated by the pointer in the first sequence, wherein the communication and transaction specific code do not comprise account numbers; (e) refusing communications having a transaction specific code that is different from the transaction specific code indicated by the pointer in the second communicating device; and (f) incrementing the pointers in a predetermined sequence within both the first and second sequences to the next transaction specific code in the absence of an interrogation transmission from the second communicating device.
2. The method of claim 1, wherein the first sequence of transaction codes is stored in a database.
3. The method of claim 1, wherein the first sequence of transaction codes is calculated.
4. The method of claim 3, wherein the second sequence of transaction specific codes is calculated.
5. The method of claim 1, wherein the first communicating device is a credit card and the second communicating device is a central clearinghouse, and wherein the device identification code is not an account number for the credit card.
6. The method of claim 1, wherein the first communicating device is a cellular telephone and the second communicating device is a cellular network.
15. A method of authenticating a communication comprising: (a) providing a first communicating device with a first identification code and a first sequence of transaction specific codes; (b) providing a host communicating device with the first identification code and the first sequence of transaction specific codes; (c) setting pointers in the first sequence of transaction specific codes of both the first communicating device and the host device at the same transaction specific code; (d) transmitting a communication from the first communicating device to the host communicating device along with the first identification code and the transaction specific code associated with the pointer in the first sequence of transaction specific codes, wherein the first identification code and the transaction specific code do not comprise an account number; (e) disallowing communications transmitted with the first identification code that have a

transaction specific code that is different from the transaction specific code associated with the pointer in the first sequence of transaction specific codes; and (f) incrementing the pointers in the first communicating device and the host communicating device in a common predetermined sequence in the absence of an interrogation transmission from the second communicating device.

16. The method of claim 15, wherein the first sequence of transaction codes is stored in a database.

17. The method of claim 15, wherein the first sequence of transaction codes is calculated.

18. The method of claim 17, wherein the second sequence of transaction specific codes is calculated.

19. A method of preventing the use of cloned device, comprising: (a) providing each of a plurality of communicating devices with a device identification code and an associated sequence of transaction specific codes; (b) providing a host communicating device with an identical copy of each of the device identification codes and the associated sequences of transaction specific codes; (c) setting pointers in the communicating device and the host device at the same transaction specific code in the sequence of transaction specific codes associated with each identification code; (d) transmitting a communication from the communicating device to the host communicating device along with the device identification code and the transaction specific code associated with the pointer in the sequence of transaction specific codes; (e) disallowing communications transmitted with the device identification code that have a transaction specific code that is different from the transaction specific code associated with the pointer in the sequence of transaction specific codes, wherein the identification codes and the transaction specific codes do not comprise an account number, and (f) incrementing the pointers in the communicating device and the host communicating device in a common predetermined sequence in the absence of an interrogation transmission from the second communicating device.

20. The method of claim 19, wherein the first sequence of transaction codes is stored in a database.

21. The method of claim 19, wherein the first sequence of transaction codes is calculated.

22. The method of claim 21, wherein the second sequence of transaction specific codes is calculated.

23. A method of communicating, comprising: (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with the transaction specific code adjacent the pointer in the first sequence without transmitting an account number; (e) refusing communications having a transaction specific code that is different from the transaction specific code adjacent the pointer in the second communicating device; and (f) incrementing the pointers in a predetermined sequence within both the first and second sequences to the next transaction specific code in the absence of an interrogation transmission from the second communicating device.

24. The method of claim 23, wherein the predetermined sequence for incrementing the pointer is the same order as the first and second sequences of transaction specific codes.

25. The method of claim 23, wherein the communication is a credit card transaction, and wherein the communication does not include an account number for the credit card.

31. The method of claim 23, further comprising the step of: after refusing a communication, resetting the pointer in the host database upon receiving a series of attempted communications having a series of transaction specific codes that match a portion of the database.

32. The method of claim 23, wherein the pointer in both databases is directed to the same field containing the same transaction specific code prior to the first communication.

34. The method of claim 23, further comprising the step of resetting the pointer in the host communicating device upon receiving a series of attempted communications having transaction specific codes that match a portion of the database.

35. A method of communicating, comprising: (a) providing a first communicating device with a first sequence of transaction specific codes; (b) providing a second communicating device with a second sequence of transaction specific codes, wherein the first and second sequences are identical; (c) setting pointers in the first and second sequences at the same transaction specific code; (d) transmitting a communication from the first communicating device to the second communicating device along with the transaction specific code adjacent the pointer in the first sequence and without transmitting an account number; (e) refusing communications having a transaction specific code that is not identical to a transaction specific code in the second communicating device within a predetermined range of fields in the sequence subsequent to the pointer in the second communicating device; and (f) incrementing the pointers in a predetermined sequence within both the first and second sequences to the next transaction specific code in the absence of an interrogation transmission from the second communicating device.

36. The method of claim 35, further comprising the step of resetting the pointer in the second communicating device to the field having a transaction specific code identical to the received transaction specific code if the field is within the predetermined range of fields subsequent to the pointer.
